Abstract

In this paper we compare Naïve Bayes (NB) models, general Bayes Net (BN) models and Probabilistic Decision Graph (PDG) models w.r.t. accuracy and efficiency. As the basis for our analysis we use graphs of size vs. likelihood that show the theoretical capabilities of the models. We also measure accuracy and efficiency empirically by running exact inference algorithms on randomly generated queries. Our analysis supports previous results by showing good accuracy for NB models compared to both BN and PDG models. However, our results also show that the advantage of the low complexity inference provided by NB models is not as significant as assessed in a previous study.

1 Introduction

Probabilistic graphical models (PGMs) have been applied extensively in machine learning and data mining research, and many studies have been dedicated to the development of algorithms for learning PGMs from data. Automatically learned PGMs are typically used for inference, and therefore efficiency and accuracy of the PGM w.r.t. inference are of interest when evaluating a learned model.

Among some of the most commonly used PGMs are the general Bayesian Network model (BN) and the Naïve Bayes model (NB). The BN model efficiently represents a joint probability distribution over a domain of discrete random variables by a factorization into independent local distributions. The NB model contains a number of *components* defined by an unobserved latent variable and models each discrete random variable as independent of all other variables within each component. Exact inference has linear time complexity in the size of the model when using NB models.

For the general BN model both exact and approximate inference are NP-hard (Cooper, 1987; Dagum and Luby, 1993).

Model-selection algorithms for learning PGMs typically use some conventional score-metric, searching for a model that optimises the metric. Penalised likelihood metrics like BIC, AIC and MDL are weighted sums of model accuracy and size. When the learned model is to be used for general inference, including a measure for inference complexity into the metric is relevant. Neither BIC, AIC nor MDL explicitly takes inference complexity into account when assessing a given model. Recently, several authors have independently emphasised the importance of considering inference complexity when applying learning in a real domain.

Beygelzimer and Rish (2003) investigate the tradeoff between model accuracy and efficiency. They only consider BN models for a given target distribution (in a learning setting, the target distribution is the empirical distribution defined by the data; more generally, the target distribution could be any distribution one wants to represent). For BNs *treewidth* is an adequate efficiency measure (defined as $k-1$, where k is the size of the largest clique in an optimal junction tree). Tradeoff curves that plot treewidth against the best possible accuracy achievable with a given treewidth are introduced. These tradeoff curves can be used to investigate the *approximability* of a target distribution.

As an example for a distribution with poor approximability in this sense, Beygelzimer and Rish (2003) mention the parity distribution, which rep-

resents the parity function on n binary inputs. An accurate representation of this distribution requires a BN of treewidth $n-1$, and any BN with a smaller treewidth can approximate the parity distribution only as well as the empty network.

The non-approximability of the parity distribution (and hence the impossibility of accurate models supporting efficient inference) only holds under the restriction to BN models with nodes corresponding exactly to the n input bits. The use of other PGMs, or the use of latent variables in a BN representation, can still lead to accurate and computationally efficient representations of the parity distribution.

Motivated by some distribution's refusal to be efficiently approximated by BN models, the PGM language of probabilistic decision graph (PDG) models was developed (Jaeger, 2004). In particular, the parity distribution is representable by a PDG that has inference complexity linear in n. In a recent study an empirical analysis of the approximations offered by BN and PDG models learned from real-world data was conducted (Jaeger et al., 2006). Similar to the tradeoff curves of (Beygelzimer and Rish, 2003), Jaeger et al. (2006) used graphs showing likelihood of data vs. size of the model for the analysis of accuracy vs. complexity. The comparison of PDGs vs. BNs did not produce a clear winner, and the main lesson was that the models offer surprisingly similar tradeoffs when learned from real data.

Also motivated by considerations of model accuracy and efficiency, Lowd and Domingos (2005) in a recent study compared NB and BN models. NB models can potentially offer accuracy-efficiency tradeoff behaviors that for some distributions differ from those provided by standard BN representation (although NBs do not include the latent class models that allow an efficient representation of the parity distribution). Lowd and Domingos (2005) determine inference complexity empirically by measuring inference times on randomly generated queries. The inferences are computed exactly for NB models, but for BN models approximate methods were used (Gibbs sampling and loopy belief propagation). Lowd and Domingos (2005) conclude that NB models offer approximations that are as accurate as those offered by BN models, but in terms of inference complexity the NB models are reported to be orders of magnitude faster than BN models.

Our present paper extend these previous works in two ways. First, we conduct a comparative analysis of accuracy vs. efficiency tradeoffs for three type of PGMs: BN, NB and PDG models. Our results show that in spite of theoretical differences BN, NB and PDG models perform surprisingly similar when learned from real data, and no single model is consistently superior. Second, we investigate the theoretical and empirical efficiency of exact inference for all models. This analysis somewhat differs from the analysis in (Lowd and Domingos, 2005), where only approximate inference was considered for BNs. The latter approach can lead to somewhat unfavorable results for BNs, because approximate inference can be much slower than exact inference for models still amenable to exact inference. Our results show that while NB models are still very competitive w.r.t. accuracy, exact inference in BN models is often tractable and differences in empirically measured run-times are typically not significant.

2 Probabilistic Graphical Models

In this section we introduce the three types of models that we will use in our experiments; the general Bayesian Network (BN), the Naïve Bayesian Network (NB) and the Probabilistic Decision Graph (PDG).

2.1 Bayesian Network Models

BNs (Jensen, 2001; Pearl, 1988) are a class of probabilistic graphical models that represent a joint probability distribution over a domain $\mathbf{X}$ of discrete random variables through a factorization of independent local distributions or factors. The structure of a BN is a directed acyclic graph (DAG) $G = (\mathbf{V}, \mathbf{E})$ of nodes $\mathbf{V}$ and directed edges $\mathbf{E}$. Each random variable $X_i \in \mathbf{X}$ is represented by a node $V_i \in \mathbf{V}$, and the factorization $\prod_{X_i \in \mathbf{X}} P(X_i | pa_G(X_i))$ (where $pa_G(X_i)$ is the set of random variables represented by parents of node V_i in DAG G) defines the full joint probability distribution $P(\mathbf{X})$ represented by the BN model. By *size* of a BN we understand the size of the *representation*, i.e. the number of independent parameters. Exact inference is usually performed by first constructing a junction tree from the BN. Inference is then solvable in time linear in the size of the junction tree (Lauritzen and

Spiegelhalter, 1988), which may be exponential in the size of the BN from which it was constructed.

2.2 Naïve Bayes Models

The NB model represents a joint probability distribution over a domain $\mathbf{X}$ of discrete random variables by introducing an unobserved, latent variable C. Each state of C is referred to as a *component*, and conditioned on C, each variable $X_i \in \mathbf{X}$ is assumed to be independent of all other variables in $\mathbf{X}$. This yields the simple factorization: $P(\mathbf{X}, C) = P(C) \prod_{X_i \in \mathbf{X}} P(X_i|C)$. Exact inference is computable in time linear in the representation size of the NB model.

2.3 Probabilistic Decision Graph Models

PDGs are a fairly new language for probabilistic graphical modeling (Jaeger, 2004; Bozga and Maler, 1999). As BNs and NBs, PDGs represent a joint probability distribution over a domain of discrete random variables $\mathbf{X}$ through a factorization of local distributions. However, the structure of the factorization defined by a PDG is not based on a variable level independence model but on a certain kind of context specific independencies among the variables. A PDG can be seen as a two-layer structure, 1) a forest of tree-structures over all members of $\mathbf{X}$, and 2) a set of rooted DAG structures over *parameter* nodes, each holding a local distribution over one random variable. Figure 1(a) shows a forest F of tree-structures over binary variables $\mathbf{X} = \{X_0, X_1 \ldots, X_5\}$, and figure 1(b) shows an example of a PDG structure based on F. For a complete semantics of the PDG model and algorithms for exact inference with linear complexity in the size of the model, the reader is referred to (Jaeger, 2004).

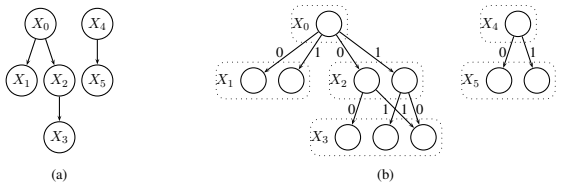

Figure 1: Example PDG. Subfigure (a) shows the a forest-structure F over binary 5 variables, and (b) shows a full PDG structure based on F.

3 Elements of the Analysis

The goal of our analysis is to investigate the quality of PGMs learned from real data w.r.t. accuracy and inference efficiency. The appropriate notion of accuracy depends on the intended tasks for the model. Following (Jaeger et al., 2006; Lowd and Domingos, 2005; Beygelzimer and Rish, 2003) we use log-likelihood of the model given the data ($L(M, D)$) as a "global" measure of accuracy. Log-likelihood score is essentially equivalent to cross-entropy (CE) between the empirical distribution P^D and the distribution P^M represented in model M:

$$CE(P^D, P^M) = -H(P^D) - \frac{1}{|D|} L(M, D), \quad (1)$$

where $H(\cdot)$ is the entropy function. Observe that when $CE(P^D, P^M) = 0$ (when P^D and P^M are equal), then $L(M, D) = -|D| \cdot H(P^D)$. Thus, data entropy is an upper bound on the log-likelihood.

3.1 Theoretical Complexity vs. Accuracy

We use SL-curves (Jaeger et al., 2006) in our analysis of the theoretical performance of each PGM language. SL-curves are plots of size vs. likelihood. The size of model here is the *effective size*, i.e. a model complexity parameter, such that inference has linear time complexity in this parameter. For NB and PDG models this is the size of the model itself. For BN models it is the size of the junction tree constructed for inference.

3.2 Empirical Complexity and Accuracy

The size measure used in the SL-curves described in section 3.1 measures inference complexity only up to a linear factor. Following Lowd and Domingos (2005), we estimate the complexity of exact inference also empirically by measuring execution times for random queries. A query for model M is solved by computing a conditional probability $P^M(\mathbf{Q} = \mathbf{q}|\mathbf{E} = \mathbf{e})$, where $\mathbf{Q}, \mathbf{E}$ are disjoint subsets of $\mathbf{X}$, and $\mathbf{q}, \mathbf{e}$ are instantiations of $\mathbf{Q}$, respectively $\mathbf{E}$. Queries are randomly generated as follows: first a random pair $\langle \mathbf{Q}_i, \mathbf{E}_i \rangle$ of subsets of variables is drawn from $\mathbf{X}$. Then, an instance d_i is randomly drawn from the test data. The random query then is $P^M(\mathbf{Q} = d_i[\mathbf{Q}_i]|\mathbf{E} = d_i[\mathbf{E}_i])$, where

$d_i[\mathbf{Q}_i], d_i[\mathbf{E}_i]$ are the instantiations of $\mathbf{Q}$, respectively $\mathbf{E}$ in d_i. The empirical complexity is simply the average execution time for random queries. The empirical accuracy is measured by averaging $log(P^M(\mathbf{Q} = d_i[\mathbf{Q}_i]|\mathbf{E} = d_i[\mathbf{E}_i]))$ over the random queries. Compared to the global accuracy measure $L(M, D)$, this can be understood as a measure for "local" accuracy, i.e. restricted to specific conditional and marginal distributions of P^M.

4 Learning

In this section we briefly describe the algorithms we use for learning each type of PGM from data. For our analysis we need to learn a range of models with different efficiency vs. accuracy tradeoffs. For *score based* learning a general λ-score will be used (Jaeger et al., 2006):

$$S_\lambda(M, D) = \lambda \cdot L(M, D) - (1 - \lambda)|M|, \quad (2)$$

where $0 < \lambda < 1$, and $|M|$ is the size of model M. Equation (2) is a general score metric, as it becomes equivalent to common metrics as BIC, AIC and MDL for specific settings of λ[1]. By optimizing scores with different settings of λ we get a range of models offering different tradeoffs between size and accuracy. Suitable ranges of λ-values were determined experimentally for each type of model using score score-based learning (BNs and PDGs).

4.1 Learning Bayesian Networks

We use the KES algorithm for learning BN models (Nielsen et al., 2003). KES performs model-selection in the space of equivalence classes of BN structures using a semi-greedy heuristic. A parameter $k \in [0 \dots 1]$ controls the level of greediness, where a setting of 0 is maximally stochastic and 1 is maximally greedy.

The λ-score used in the KES algorithm uses the size of the BN as the size parameter $|M|$, not the size of its junction tree. Clearly, it would be desirable to score BNs directly by the size of their junction trees, but this appears computationally infeasible. Thus, our SL-curves for BNs do not show for a given accuracy level the smallest possible size of a junction tree achieving that accuracy, but the size of a junction tree we were able to find using existing state-of-the-art learning and triangulation methods.

[1] E.g. (2) with $\lambda = \frac{log|D|}{2+\log|D|}$ corresponds to BIC

4.2 Learning Naïve Bayes Net Models

For learning NB models we have implemented a version of the NBE algorithm (Lowd and Domingos, 2005) for learning NB models. As the structure of NB models is fixed, the task reduces to learning the number of states in the latent variable C, and the parameters of the model. Learning in the presence of the latent components is done by standard Expectation Maximization (EM) approach, following (Lowd and Domingos, 2005; Karciauskas et al., 2004). Learning a range of models is done by incrementally increasing the number of states of C, and outputting the model learned for each cardinality. In this way we obtain a range of models that offer different complexity vs. accuracy tradeoffs. Note that no structure-score like (2) is required as the structure is fixed.

4.3 Learning Probabilistic Decision Graphs

Learning of PDGs is done using the model-selection algorithm presented in (Jaeger et al., 2006). Using local transformations as search operators, the algorithm performs a search for a structure that optimises λ-score.

5 Experiments

We have produced SL-curves and empirically measured inference times and accuracy, on 5 different datasets (see table 1) from the UCI repository[2]. These five datasets are a representative sample of the 50 datasets used in the extensive study by Lowd and Domingos (2005).

We used the same versions of the datasets as used by Lowd and Domingos (2005). Specifically, the partitioning into training (90%) and test (10%) sets was the same, continuous variables were discretized into five equal frequency bins, and missing values were interpreted as special states of the variables.

For measuring the empirical efficiency and accuracy, we generated random queries as described in 3.2 consisting of 1 to 5 query variables $\mathbf{Q}$ and 0 to 5 evidence variables $\mathbf{E}$.

[2] `http://www.ics.uci.edu/~mlearn`

Table 1: Datasets used for experiments.

Dataset	#Vars	training	test
Poisonous Mushroom	23	7337	787
King, Rook vs. King	7	25188	2868
Pageblocks	11	4482	574
Abalone	9	3758	419
Image Segmentation	17	2047	263

For inference in BN and NB models we used the junction-tree algorithm implemented in the inference engine in Hugin[3] through the Hugin Java API. For inference in PDGs, the method described in (Jaeger, 2004) was implemented in Java. BN and NB experiments were performed on a standard laptop, 1.6GHz Pentium CPU with 512Mb RAM running Linux. PDG experiments were performed on a Sun Fire280R, 900Mhz SPARC CPU with 4Gb RAM running Solaris 9.

6 Results

Table 2 shows SL-curves for each dataset and PGM, both for training (left column) and test sets (right column).

Lowd and Domingos (2005) based their comparison on single BN and NB models. The NB models were selected by maximizing likelihood on a hold-out set. Crosses $\times$ in the right column of table 2 indicate the size-likelihood values obtained by the NB models reported in (Lowd and Domingos, 2005).

The first observation we make from table 2 is that no single model language consistently dominates the others. The plots in the left column shows that BN models have the lowest log-likelihood measured on training data consistently for models larger than some small threshold. For Abalone and Image Segmentation, this characteristic is mitigated in the plots for the test-data, where especially PDGs seem to overfit the training-data and accordingly receives low log-likelihood score on the test-data.

The overall picture in table 2 is that in terms of accuracy, BNs and NBs are often quite similar (King, Rook vs. King is the only exception). This is consistent with what Lowd and Domingos (2005) have found. However, Lowd and Domingos (2005) reported big differences in inference complexity when comparing exact inference in NB to approximate methods in BNs. We do not observe this tendency when considering exact inference for both BNs and NBs. Our results show that we can learn BNs that are within reach of exact inference methods, and that the theoretical inference complexity as measured by effective model size mostly is similar for a given accuracy level for all three PGM languages.

Effective model size measures actual inference time only up to a linear factor. In order to determine whether there possibly are huge (orders of magnitude) differences in these linear factors, we measure the actual inference time on our random queries. The left column of table 3 shows the average inference time for 1000 random queries with 4 query and 3 evidence variables (results for other numbers of query and evidence variables were very similar). We observe that this empirical complexity behaves almost indistinguishably for BN and NB models. This is not surprising, since both models use the Hugin inference engine [4]. The results do show, however, that the different structures of the junction trees for BN and NB models do not have a significant impact on runtime. The linear factor for PDG inference in these experiments is about 4 times larger than that for BN/NB inference[5]. Seeing that we use a proof-of-concept prototype Java implementation for PDGs, and the commercial Hugin inference engine for BNs and NBs, this indicates that PDGs are competitive in practice, not only according to theoretical complexity analyses.

The right column in table 3 shows the empirical (local) accuracy obtained for 1000 random queries with 4 query and 3 evidence variables. Overall, the results are consistent with the global accuracy on the test data (table 2, right column). The differences observed for the different PGMs in table 2 can also be seen in table 3, though the discrepancies tend

[3] `http://www.hugin.com`

[4] Zhang (1998) shows that variable elimination can be more efficient than junction tree-based inference. However, his results do not indicate that we would obtain substantially different results if we used variable elimination in our experiments.

[5] This factor has to be viewed with caution, since PDG inference was run on a machine with a slower CPU but more main memory. When running PDG inference on the same machine as NB/BN inference, we observed overall a similar performance, but more deviations from a strictly linear behavior (in table 3 still visible to some degree for the Mushroom and Abalone data). These deviations seem mostly attributable to the memory management in the Java runtime environment.

Table 2: SL-curves for train-sets (left column) and test-sets (right column). The crosses $\times$ marks the NB models reported by Lowd and Domingos (2005). $-H(D)$ (minus data-entropy) is plotted as a horizontal line.

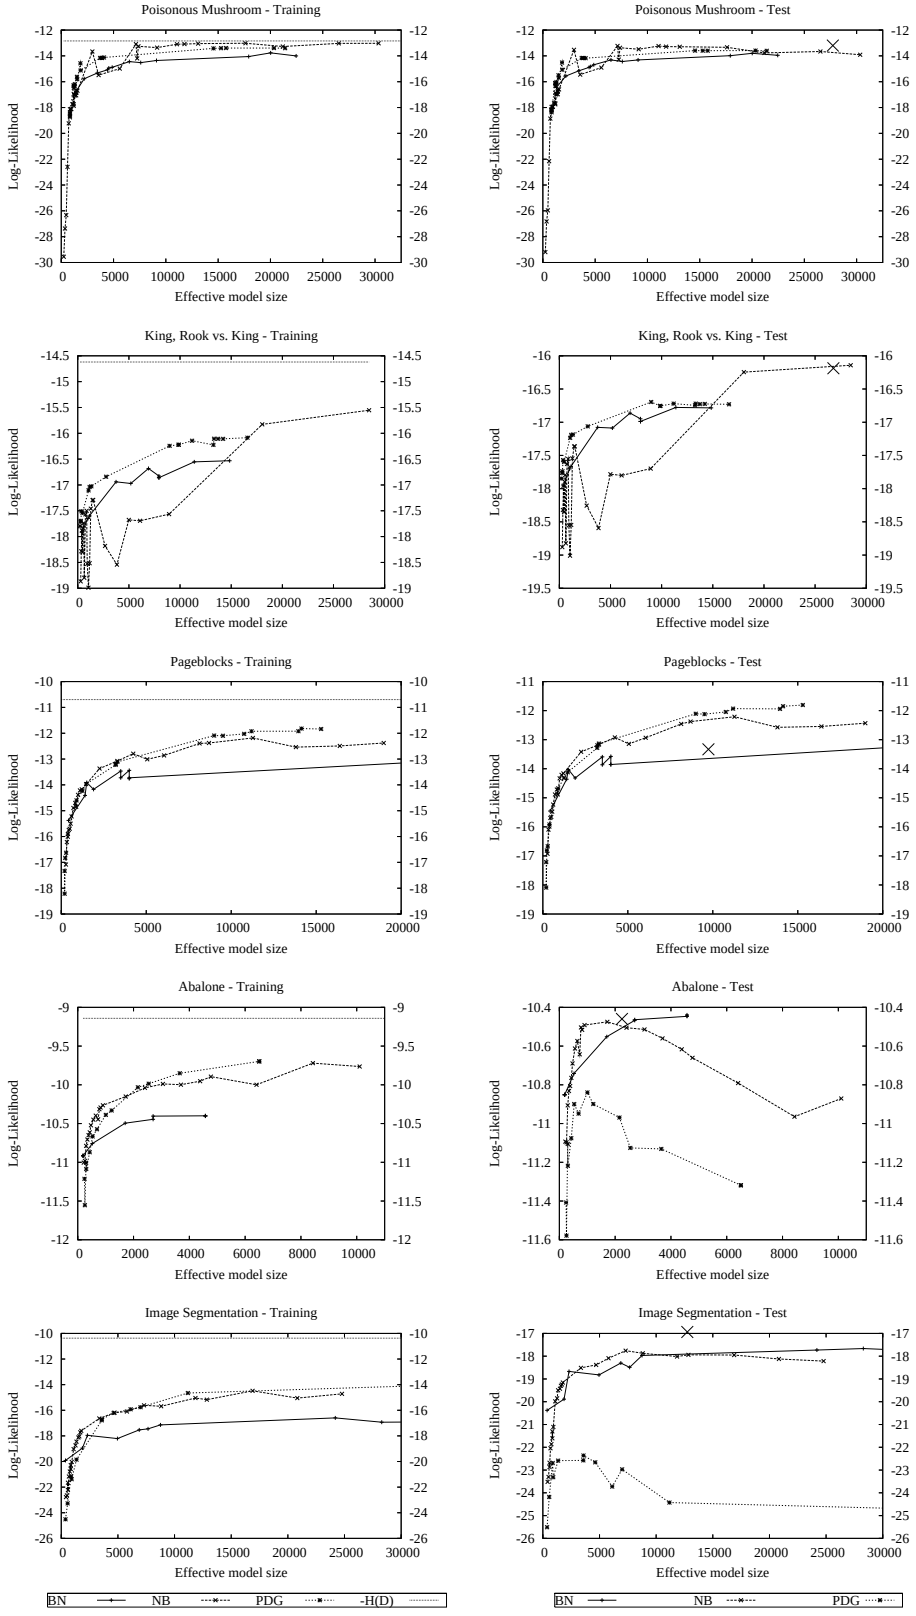

Table 3: Empirical efficiency (left column) and accuracy (right column) for 4 query and 3 evidence variables.

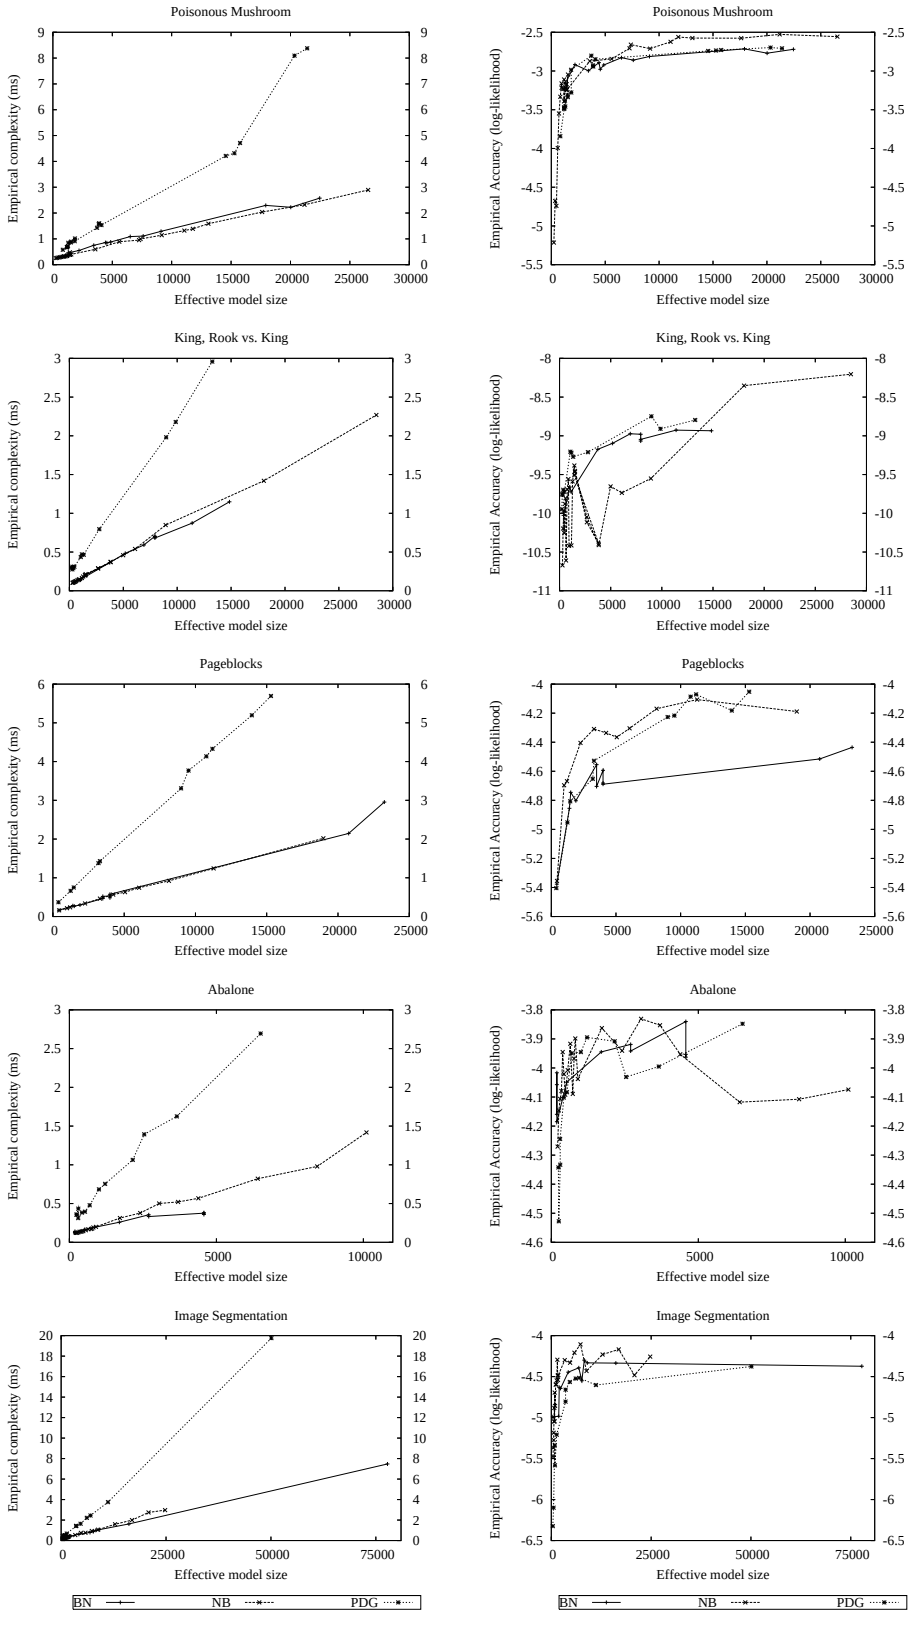

to become less pronounced on the random queries as on global likelihood (particularly for PDGs in the image segmentation data). One possible explanation for this is that low global likelihood scores are mostly due to a few test cases whose joint instantiation of the variables are given low probability by a model, and that these isolated low-probability configurations are seldom met with in the random queries.

7 Conclusion

Motivated by several previous, independent studies on the tradeoff between model accuracy and efficiency in different PGM languages, we have investigated the performance of BN, NB, and PDG models. Our main findings are: 1) In contrast to potentially widely different performance on artificial examples (e.g. the parity distribution), we observe a relatively uniform behavior of all three languages on real-life data. 2) Our results confirm the conclusions of Lowd and Domingos (2005) that the NB model is a viable alternative to the BN model for general purpose probabilistic modeling and inference. However, the order-of-magnitude advantages in inference complexity could not be confirmed when comparing exact inference methods for both types of models. 3) Previous theoretical complexity analyses for inference in PDG models now have been complemented with empirical results showing also the practical competitiveness of PDGs.

Acknowledgment

We thank Daniel Lowd for providing the preprocessed datasets we used in our experiments. We thank the AutonLab at CMU for making their efficient software libraries available to us.
